Lipid productivity

ABSTRACT

The target of rapamycin (TOR) signaling pathway regulates fundamental intracellular functions critical for cell viability and proliferation. Manipulation of TOR in high lipid-producing microalgae may help overcome the trade-off between biomass production and lipid yield that still impairs the viable production of biofuel from microalgae. In this study, we inhibited the TOR kinase in the model diatom *Phaeodactylum tricornutum* using the selective TOR inhibitor AZD-8055, and analyzed cell proliferation, chlorophyll content, lipid synthesis and carbon metabolism. AZD-8055 inhibits cell proliferation in a dose-dependent manner compared to N deprivation which stops growth. Microscopy, flow cytometry, and quantitative analyses of lipids also demonstrated that AZD-8055 treatment strongly promotes triacylglycerol (TAG) accumulation while decreasing the quantity of sterols. The TAG productivity of AZD-8055 treated cultures was significantly higher than for N deprived cultures. Measurement of the activities of the key metabolic enzymes glyceraldehyde phosphate dehydrogenase (GAPDH), glucose-6-phosphate dehydrogenase (G6PDH) and malate dehydrogenase (MDH) revealed opposite effects for AZD-8055 treatment and N-starvation on the activity of the glycolytic enzyme GAPDH. This suggests that TOR inhibition and N starvation may have distinct impacts on general metabolism and lipid accumulation. Our main finding is that treating cultures with AZD-8055 results in higher TAG productivity than N starvation in *P. tricornutum*. The chemical or genetic manipulation of the TOR signaling pathway in *P. tricornutum* and other diatoms may lead to the development of strains or approaches suitable for the enhanced production of TAGs for biofuel.

1. Introduction

Since the second half of the XIX century the use of natural resources, like fossil fuels, gas and coal for sustaining human activities has been experiencing exponential growth. Although this historical phenomenon, known as the Industrial Revolution, had beneficial effects on human society, it has also led to long-term catastrophic effects on the environment with consequences for human health. Combustion of fossil fuels is indeed one of the main factors responsible for greenhouse gases emissions (CO₂) and atmospheric release of toxic compounds, which in turn are involved in global warming, ocean acidification and various types of diseases [1,2]. The search for sustainable and less polluting

energy alternatives has now become a mission of paramount importance. Third-generation biofuels from microalgae reconcile the high demand for liquid fuels with many of the technical problems encountered in other oil-producing organisms like crops [3]. While unicellular photosynthetic organisms represent only about 0.2% of the global biomass, they account for almost 50% of the global net primary production [4] and the energy that they can store in the form of lipids represents > 20% of dry weight under nutrient-sufficient growth conditions [5]. This percentage can rise to 70–80% in some species of eukaryotic microalgae under nutrient limitation [3].

Diatoms (*Bacillariophyceae*) are the predominant class of eukaryotic microalgae in the oceans, where they account for about 40% of net

primary production (the remainder accounted by other eukaryotic organisms and cyanobacteria; [6]), and possess qualities (high photosynthetic efficiency, fast growth and the capacity to store energy and carbon in the form of neutral lipids) that make them one of the most suitable groups for biofuel production [7,8]. The advanced genetic engineering tools developed in the diatom *Phaeodactylum tricornutum*, whose genome is known [9–13], make it one of the preferred model microalgae for biotechnology studies. In spite of this, biofuel production from microalgae is still a challenging process as the highest lipid accumulation per cell is achieved when the algae are subject to stress conditions like nitrogen starvation [14], which ultimately limits the overall biomass and thus lipid yield. The study and manipulation of signaling pathways regulating cell growth and metabolism, for instance, the target of rapamycin (TOR) pathway, may help to combine high lipid yields with the maintenance of cell proliferation. TOR manipulation for biofuel production was first proposed in a study showing that TOR repression in *Arabidopsis thaliana* artificial microRNA (amiR) lines affects carbon metabolism and results in starch and TAG accumulation associated with growth repression [15]. Further studies showed that TOR inhibitors could induce TAG accumulation in the red alga *Cyanidioschyzon merolae* and the green alga *Chlamydomonas reinhardtii* [16,17]. However, TAGs were measured only at TOR inhibitor concentrations that stop proliferation and TAG productivity was not studied. A recent study on *Euglena gracilis*, a distant alga belonging to the Excavata, reported that the TOR inhibitor rapamycin has little effect on proliferation, yet could induce a 1.4-fold increase in neutral lipids per cell [18]. This suggests that TOR inhibition could be a route to increasing TAG productivity in some algae. The TOR signaling network plays a key role in the regulation of cell growth integrating the responses to a variety of signals, like nutrient levels and stress, and transmitting them to the metabolic machinery (reviewed in [19,20]). TOR is a large protein kinase belonging to the phosphatidylinositol kinase-related kinase (PIKK) family that includes the checkpoint kinases ataxia telangiectasia mutated (ATM) and ATM- and RAD3-related protein (ATR), which are master controllers of cell cycle signaling pathways [21]. TOR can be found in two multiprotein complexes, TORC1 and TORC2 [19]. While TORC2, involved in cytoskeleton organization in animals and yeast, is not conserved in Viridiplantae and diatoms, TORC1 is found in all eukaryotes, with the exception of intracellular parasites, thus indicating a fundamental role for TORC1 in eukaryotes [22]. TORC1 is stimulated by nutrients and inhibited by stress-related signals [23]. The conserved function of active TORC1 is to activate protein synthesis, cell-cycle progression, and energy metabolism, while inhibiting stress responsive genes and autophagy. In yeast and animal cell lines, TOR inhibition blocks cell division, increases autophagy resulting in altered cell physiology, fate and morphology in manner reminiscent of a nutrient-starvation response [24]. In addition to a potential application in biofuel production, the study of TOR signaling in diatoms is of fundamental importance as the evolution of the TOR pathway in algae with secondary plastids might have been influenced by the multiple endosymbiosis events that characterized their evolution [9].

In this study, we used a synthetic and highly specific ATP-competitive inhibitor of the TOR kinase known as AZD-8055 [28] to test how modulating TOR activity affects cell proliferation, TAG accumulation and productivity, and primary metabolism in *P. tricornutum*. Two other TOR inhibitors, rapamycin and WYE-132, were also used to evaluate the specificity of this response towards TOR inhibition.

2. Materials and methods

2.1. Algal strain and AZD-8055 treatment

P. tricornutum Pt1_8.6 (RCC 2967) was grown for eight days at 18 °C in F/2 medium [29] supplemented with silica (F/2 + Si medium) in an incubator equipped with a shaking plate (Innova 4230, New Brunswick

Scientific, Edison NJ, USA). Irradiance was kept at 80 mol photons $m^{-2} s^{-1}$ for 14 h day^{-1} . For the AZD-8055 treatments, a culture of *P. tricornutum* from an early exponential phase was diluted to $OD_{750} \approx 0.003$ in a 5-l Erlenmeyer flask containing 2.5 l of fresh F/2 + Si medium. The OD_{750} was measured daily until it reached ≈ 0.03 (after 72 h), a value corresponding to the beginning of the exponential phase for this strain; the culture was then split into nine 1-l Erlenmeyer flasks containing 250 ml of medium each. The TOR inhibitor AZD-8055 (Chemdea, Ridgewood, NJ, USA; [28]) was then added to a final concentration of 0.001, 0.01, 0.1, 1, 2, 4 and 10 $mol\ l^{-1}$. The inhibitor was dissolved in dimethyl sulfoxide (DMSO), whose final concentration was adjusted to 0.1% for each of the different cultures and the control. The ninth part of the initial culture was subjected to nitrogen starvation. For N starvation, cells were centrifuged at 3500g for 15 min, the supernatant discarded and the pellet washed three times in N-free F/2 + Si medium; the pellet was then resuspended in 250 ml of fresh N-free F/2 + Si medium. Three independent experiments were conducted for each culture condition. Another set of experiments was performed to compare the effect of high concentrations of AZD-8055 and other TOR inhibitors on cell proliferation and neutral lipid content in *P. tricornutum*. Cultures were grown as described above. The TOR inhibitors AZD-8055 (10 and 40 $mol\ l^{-1}$), rapamycin (10 $mol\ l^{-1}$; LC Laboratories, Woburn, MA, USA) and WYE-132 (5 $mol\ l^{-1}$; Chemdea, Ridgewood, NJ, USA) were added to early exponential phase cells as described above.

2.2. Cell fixation and Nile red staining

Each day a volume of *P. tricornutum* culture, varying from 5 to 200 ml depending on biomass production, was harvested by centrifugation at 3500 g for 15 min. The pellet was resuspended in 0.5 ml of a fixing solution containing HEPES (0.1 $mol\ l^{-1}$, pH 7), $CaCl_2$ (0.01 $mmol\ l^{-1}$), $MgCl_2$ (0.01 $mmol\ l^{-1}$) and glutaraldehyde 2% (v/v). After one hour incubation at 4 °C in the dark, the fixing solution was removed and the cells resuspended in 1 ml of HEPES (0.1 $mol\ l^{-1}$, pH 7). The samples were stored at 4 °C in the dark.

For visualization of neutral lipids, the fixed cells were incubated with a Nile red solution (FluoProbes, Interchim; 488–530/575–580 nm excitation/emission; [30]) and analyzed by fluorescence microscopy and analytical flow cytometry. A 0.25 $mg\ ml^{-1}$ Nile red solution in DMSO was added to the fixed cell suspensions to a final concentration of 1 $g\ ml^{-1}$ [31]. The mixtures were incubated at 4 °C for 5 min prior to analysis.

2.3. Flow cytometry

A benchtop flow cytometer (BD Accuri C6, BD Biosciences, Ann Arbor, MI, USA) was used to assess *P. tricornutum* cell abundance during the whole course of the experiments. The instrument is equipped with two excitation laser beams emitting at 488 and 640 nm. The flow cytometer measures chlorophyll red fluorescence (CHL, > 675 nm; channel FL3), orange fluorescence (PE, 585 ± 20 nm; channel FL2), green fluorescence (530 ± 15 nm; channel FL1), side scatter (SSC, light scattered by particles at 90° to the direction of the laser beam) and forward light scatter (FSC, light scattered by particles at narrow angles in the same direction as the laser beam). Their combination allows detecting different wavelength emission ranges [32]. Diatom density was estimated by the cytogram forward scatter (FSC) versus channel FL3, whereas side scatter (SSC) combined with the FL3 channel was used to estimate chlorophyll auto-fluorescence. The specific growth rate for each culture condition was calculated on the exponential portion of the growth curve, according to the equation of Monod [33]. It has been demonstrated that lipid fluorescence in microalgae estimated through the combination of Nile red staining and flow cytometry shows a positive correlation with the content of lipids quantified by thin layer chromatography [34]. We then performed flow cytometry analyses on

the fixed cell after Nile red staining in order to assess neutral lipid content in *P. tricornutum*. In this case, the trigger signal was set up on FL2 fluorescence and combined with the SSC signal. For all measurements of cell density, chlorophyll and lipid fluorescence the cytometer flow rate was kept constant at 35 l min^{-1} . All data were normalized using BD TruCount beads; a 50 ml aliquot containing a known number of beads diluted in ultrapure water (Carlo Erba Reagents, Milan, Italy) was added to each sample and the bead abundance and fluorescence measured simultaneously with those of the microalgae. Control of the cytometer, measurements of light scatter and fluorescence intensities, data storage in list mode format and subsequent data analysis were performed using the CFlow Plus software (BD Biosciences) with log amplification on a seven-decade scale.

2.4. Epifluorescence microscopy

In order to confirm the presence of oil bodies in AZD-8055 treated cells, fixed and Nile red-stained cells of *P. tricornutum* from each culture condition were observed under an epifluorescence microscope (Axiovert 200M, Carl Zeiss Microscopy GmbH, Jena, Germany) at an excitation wavelength of $\approx 480 \text{ nm}$. At least three random pictures per sample were acquired. Nile red and chlorophyll fluorescence were adjusted to the background a posteriori using the AxioVision image-processing software version 4.8.2-SP2.

2.5. Lipid extraction, quantification and productivity

At day 5 of growth and for each culture condition, approx. 150 ml of cell culture was harvested by centrifugation at 3500g for 15 min at 4°C in order to carry out lipid quantification. The pellets were directly resuspended in 3 ml of a chloroform/methanol mixture (2:1, v/v) and 0.2 ml of 1 mol l^{-1} HCl and frozen at -20°C . This procedure prevents artefactual lipolysis that often occurs upon cell disruption. A freezing/thawing step followed by vigorous vortex stirring and sonication with 10 pulses for 10 times using an ultrasonicator (Sonic 671 Ruptor 250, OMNI International, Kennesaw, GA, USA) further allowed breaking the diatom cells. The samples were then mixed with 0.5 ml of ultrapure water and stirred vigorously to complete lipid extraction. The mixtures were centrifuged at 1000g for 10 min at 4°C to allow complete phase separation; the lower organic phase containing lipids was collected and dried over anhydrous MgSO_4 to trap residual water. The clear organic phase was collected, transferred to a 5-ml glass vial and evaporated under a nitrogen stream. The dried lipid extracts were kept at -20°C before analysis. Neutral lipids were separated by thin layer chromatography on silica-coated quartz rods (SIII Chromarods) and detected by flame ionization using a MK-6 Iatroscan TLC-FID apparatus (Iatron Laboratories, Tokyo, Japan) as described previously [35]. Data acquisition and processing were performed using the i-Chromstar 6.3 integration software (SCPA GmbH, Bremen, Germany). The amounts of TAGs, free fatty acids (FFAs), monoacylglycerols (MAGs), diacylglycerols (DAGs) and free sterols were estimated from calibration curves established, respectively, with pure triolein, oleic acid, 1-monoolein, 1,2(2,3)-diolein, [35] and cholesterol [36] as reference standards. Sterols were also separated by classical TLC and analyzed by gas chromatography coupled to mass spectrometry (GC–MS) for identification. Total lipid extracts were first loaded and separated on a thin-layer Silica Gel 60 plate ($10 \times 20 \text{ cm}$ from Merck) using a hexane/diethyl ether/acetic acid (60:40:1; v/v/v) solvent mixture. The silica band corresponding to sterols on the TLC plate was scrapped and washed with chloroform/methanol (2:1 v/v) to recover the sterols. After solvent evaporation under nitrogen, sterols were derivatized using $100 \mu\text{l}$ Bis(trimethylsilyl)trifluoroacetamide (BSTFA) at 80°C for 30 min. Samples were then analyzed by GC–MS using an Agilent Technologies HP 6980 gas chromatograph equipped with a (50%-phenyl)-methylpolysiloxane ($60 \text{ m} \times 0.25 \text{ mm ID} \times 0.25 \mu\text{m film}$) DB-17MS column and a HP5973 mass spectrometer. Separation was

achieved by injecting $1 \mu\text{l}$ of each derivatized sample. The carrier gas was helium at an input pressure of 119 kPa. The temperature of the split/splitless injector and interface was set at 280°C . The oven temperature was kept at 57°C for 2 min before ranging to 180°C at a rate of 20°C/min , and then to 300°C at a rate of 4°C/min . Temperature was then held for 30 min before returning to initial conditions. Mass analysis was performed with an electron impact (EI) source set at 70 eV and 280°C , under SCAN mode from 70 to 800 m/z , and with a quadrupole detector at 150°C . Brassicasterol (Sigma-Aldrich B4936) was used as an external standard for quantification. Data were normalized to the cell dry weight measured from 50 ml of *P. tricornutum* sampled at the same time the cells were harvested for lipid analysis; the pellets were washed twice with ammonium bicarbonate 0.4 mol l^{-1} to eliminate residual salts, dried overnight at 80°C (Thermo Fisher Scientific, Waltham, MA USA) and finally weighed with a precision scale.

TAG productivity was calculated as described in Hempel et al. [37] using the following equation:

$$P_{\text{TAG}}(\text{mg l}^{-1} \text{ day}^{-1}) = P_{\text{B}} C_{\text{f}}$$

where P_{TAG} is TAG productivity, P_{B} is biomass productivity, calculated as biomass increase over time ($\text{g l}^{-1} \text{ day}^{-1}$), and C_{f} is TAG final concentration (% of dry weight) [37].

2.6. Protein extraction and enzyme assays

About 250 ml of cells, at growth day 5 after AZD-8055 addition or N deprivation, were collected by centrifugation at 3500g for 15 min at 4°C . The pellets were washed twice with Tris/EDTA buffer (30 and 4 mmol l^{-1} respectively) at pH 7.9, then resuspended in Tris/EDTA buffer plus cysteine (5 mmol l^{-1}), NAD^+ (0.1 mmol l^{-1}) and protease inhibitor cocktail (0.5 mg ml^{-1} ; P2714, Sigma-Aldrich, Saint Louis, MO, USA). The cell suspensions were sonicated for 4 cycles, 10/30 s on/off (Sonic 671 Ruptor 250, OMNI International, Kennesaw, GA, USA), and, after the addition of 10% glycerol, centrifuged at 12000g for 20 min at 4°C . The crude extracts were used for both total protein quantification with the Bradford assay [38] and enzyme activity measurements.

All enzyme assays were conducted at pH 7.7 in 50 mmol l^{-1} glycylglycine, 0.5 mmol l^{-1} EDTA, 50 mmol l^{-1} KCl and 15 mmol l^{-1} MgCl_2 . The activities of glyceraldehyde phosphate dehydrogenase (GAPDH), glucose-6-phosphate dehydrogenase (G6PDH) and malate dehydrogenase (MDH) were measured spectrophotometrically at 340 nm as described in Mekhalfi et al. [8].

2.7. Data analysis and statistics

All graphs and statistical tests were performed with SigmaPlot version 11.0 (Systat Software, Chicago, IL, USA). Error bars correspond to standard deviations calculated on three biological and three technical replicates. Statistical significance was calculated using the analysis of variance (one-way ANOVA) followed by the Holm-Šidák multiple comparisons test.

3. Results

3.1. AZD-8055 inhibits *P. tricornutum* growth in a dose-dependent manner

The *P. tricornutum* genome contains a single TOR gene (Fig. S1). The motifs and amino acids of the ATP-binding pocket of the TOR kinase domain are highly conserved in *P. tricornutum* compared to mammals (Fig. S2), indicating that specific ATP-competitive TOR inhibitors developed for mammalian cells should be potent in *P. tricornutum*. We tested AZD-8055 because this inhibitor is highly selective for TOR and is potent in a wide range of species, including plants and green algae [16,25]. Flow cytometry was used to directly measure the effect of AZD-8055 on cell proliferation. Treatment with AZD-8055 caused a

clear inhibition of *P. tricornutum* cell proliferation in a dose responsive manner, with 30% inhibition at 2 and 4 μ M and 80% inhibition at 10 μ M (Fig. 1A). The time course of the effects of AZD-8055 on *P. tricornutum* growth curves and doubling times are reported in comparison with N starvation (Fig. 1B and Table 1). The typical growth curve of *P. tricornutum* in the control showed a 3-day lag phase followed by four days of exponential growth. The average doubling time was 17 ± 1 h⁻¹ during the exponential phase. AZD-8055 did not appear to affect either the growth curve shape or the growth rate at

concentrations up to 1 mol l⁻¹. AZD-8055 concentrations of 2 and 4 mol l⁻¹ resulted in a modest, but reproducible, inhibition of growth and, unlike the control, these cultures had not yet reached the stationary phase after 5 days of cultivation (Fig. 1B and S3, Table 1). *P. tricornutum* growth was strongly and reproducibly affected by 10 mol l⁻¹ AZD-8055 with a doubling time of almost half that of the control (Table 1) and a final density of 20% of the control, corresponding to 80% inhibition of cell proliferation. N starvation had an even more drastic effect than 10 mol l⁻¹ AZD-8055 with a doubling time 3 times longer than the control and a final density of only 5% of the control, corresponding to 95% inhibition of cell proliferation (Fig. 1B and Table 1). These results show that *P. tricornutum* cell proliferation can be robustly modulated using different concentrations of the TOR inhibitor AZD-8055.

3.2. AZD-8055 promotes the accumulation of neutral lipids in lipid droplets

Nile red staining was used to investigate variations in neutral lipid content by flow cytometry and fluorescence microscopy. The quantification of neutral lipids by Nile red fluorescence showed a strong correlation with the quantification of TAGs by TLC-FID (Peterson $r = 0.97$; Fig. S4), confirming the reliability of Nile red fluorescence as a fast and simple method to estimate neutral lipid abundance in microalgae, especially when handling large datasets [31,34]. Fluorescence analysis revealed that neutral lipid content did not vary in cells treated with AZD-8055 up to a concentration of 1 mol l⁻¹ with respect to the control (Fig. 2A). In contrast, at higher concentrations of AZD-8055 (2, 4 or 10 mol l⁻¹), neutral lipid accumulation was rapidly triggered and the fluorescence signal reached almost 4-fold the level of the control after one day. Neutral lipid content continued increasing at these higher AZD-8055 concentrations and reached very similar values of about 20-fold higher at day 5. This increase in neutral lipids was less rapid for 2 mol l⁻¹ AZD-8055 than for 4 and 10 mol l⁻¹ showing a dose dependent effect on the timing of neutral lipid accumulation. N starved cells showed an earlier and higher accumulation of neutral lipids with a 10-fold higher signal than the control at day 1 and 100-fold higher at day 5.

These data were confirmed by fluorescence microscopy, which showed visible differences in the number and size of Nile red stained lipid droplets within cells (Fig. 2B and S5). No lipid droplets could be observed in either the control or cells treated with up to 1 mol l⁻¹ of AZD-8055 (Fig. 2B and S5). On the contrary, in cells treated with AZD-8055 2, 4 and 10 mol l⁻¹, numerous small lipid droplets appeared from the first day of treatment (Fig. S5). By the end of the experiment (Fig. 2B), lipid droplets almost filled the interior of cells that had been treated with the highest concentration of AZD-8055. In cells subjected to N starvation, large lipid droplets developed after one day of treatment and became the most prevalent part of the cell by day 5. In summary, cells treated with 2 to 10 μ M AZD-8055 progressively accumulated high levels of neutral lipids in droplets, and these changes did not occur as early or as strongly as in N starved cells.

3.3. AZD-8055 enhances TAG productivity compared to N starvation

Neutral lipids were extracted from early stationary phase cells collected at day 5 after addition of AZD-8055 or N starvation, separated, and quantified by TLC-FID. In agreement with flow cytometry and fluorescence microscopy data, TAG content (Fig. 3A) did not change significantly in cells treated with AZD-8055 up to 1 mol l⁻¹ compared to the control, where TAG represented 0.1% of total dry biomass. However, in cells treated with 2, 4 and 10 mol l⁻¹ of AZD-8055, TAG content reached 3–7% of total dry biomass. It is also noteworthy that the TAG contents in cells treated with the three highest concentrations of AZD-8055 were not statistically different from each other. In accordance with the flow cytometry data, TAG content was considerably higher in N-starved cells (24% of total dry biomass). However, for

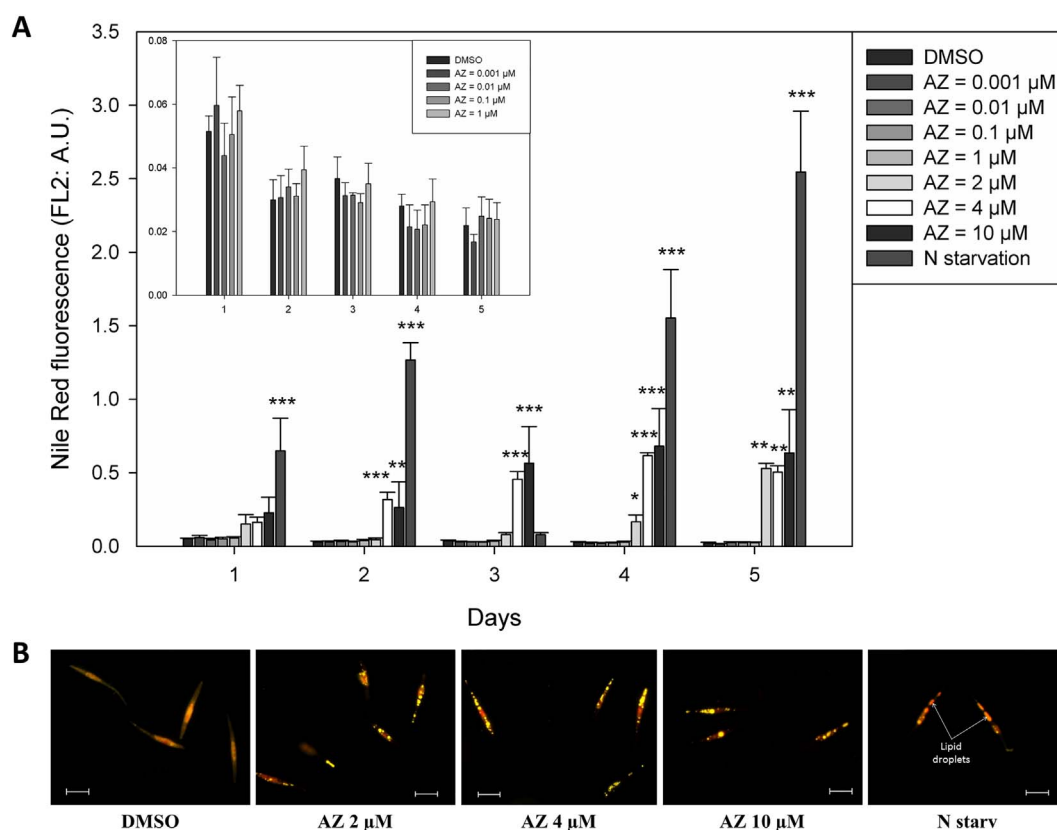

Fig. 2. Effect of AZD-8055 and N starvation on neutral lipid fluorescence and lipid droplet accumulation. A) Lipid estimation after Nile red staining measured with the flow cytometer. The x axis depicts the days after treatment with either DMSO or AZD-8055 (AZ) addition or after transfer into N-free medium. Means of three biological and three technical replicates are shown \pm standard deviation. Asterisks indicate statistical significance with respect to the control (* = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$). B) Fluorescence microscopy of *P. tricornutum* after Nile red staining at day 5. Lipid droplets are indicated by the yellow fluorescence, while the red fluorescence corresponds to chlorophyll auto-fluorescence. The scale bars correspond to 10 μ m length in all pictures. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

biofuel applications the quantity of TAG expressed on a per cell basis or as a percentage of dry weight is not as important as the TAG productivity of the total culture. We found that TAG productivity started to increase around 1 mol l^{-1} AZD-8055 and strongly increased to values almost 100 times higher than control cells in cells treated with 2 to 10 μ M AZD-8055. Strikingly, TAG productivity was much higher than for N-starved cells (about 3–4 times higher; Fig. 3B). This higher TAG productivity can be explained by the fact that the TOR inhibitor did not affect cell proliferation as much as N starvation and allowed the accumulation of a greater total biomass. Indeed, TAG productivity is maximal at AZD-8055 concentrations that reduce cell proliferation to 40–50% of the control, while N starvation reduces cell proliferation to 5% of the control.

3.4. AZD-8055 decreases sterol content

TLC-FID analysis of other neutral lipids showed low levels of free fatty acids (FFAs), monoacylglycerols (MAGs) and diacylglycerols (DAGs) (below the limit of quantification, data not shown). Only total sterols of *P. tricornutum* could be quantified based on a calibration curve established with cholesterol (Fig. 3C). GC-MS analysis confirmed that *P. tricornutum* sterols were almost exclusively constituted of brassicasterol, whatever the conditions. Compared to the control, sterol content was almost unaffected in cells treated with concentrations of AZD-8055 at or below 0.1 mol l^{-1} , but decreased significantly at AZD-8055 concentrations of 1, 2 and 4 mol l^{-1} . Compared to the dose response curve of TAG content, the sterol dose response was shifted to lower AZD-8055 concentrations, suggesting that inhibition of sterol accumulation precedes TAG accumulation. At an AZD-8055 concentration of 10 mol l^{-1} , the level of sterols became too low to be quantified, as was also

observed for cells under N starvation. High concentrations of AZD-8055 and N starvation, therefore, provoked a large decrease in total sterol/brassicasterol content while TAG accumulated. This reveals a correlation between the decrease in sterols and growth inhibition and an inverse correlation between the accumulation of TAGs and sterols.

3.5. AZD-8055 reduces chlorophyll fluorescence more strongly than N starvation

During the microscopic observation of Nile red stained cells, we observed less chlorophyll fluorescence from the chloroplasts of cells treated with high concentrations of AZD-8055 (Fig. 2B). This led us to analyze variations in *P. tricornutum* chlorophyll fluorescence in response to the treatment with AZD-8055 and N starvation (Fig. 3D). Chlorophyll fluorescence did not vary significantly in cells treated with AZD-8055 at concentrations up to 4 mol l^{-1} . However, at 10 mol l^{-1} AZD-8055 the average chlorophyll fluorescence was significantly lower from the first day after treatment and progressively decreased to less than half the level of the control at day 5. In cells subjected to N starvation, chlorophyll fluorescence decreased slightly but significantly 1 day after treatment and remained constant for the following days. Therefore, despite the more drastic growth inhibition, N starved cells maintained two-fold higher chlorophyll fluorescence than cells treated with 10 μ M AZD-8055. This higher chlorophyll fluorescence may at least partially explain why, although present, clear lipid droplets (bright yellow) were not visible in all N starved cells (Fig. 2B and S4). Interestingly, these data also show that high TAG productivity is not associated with higher chlorophyll content.

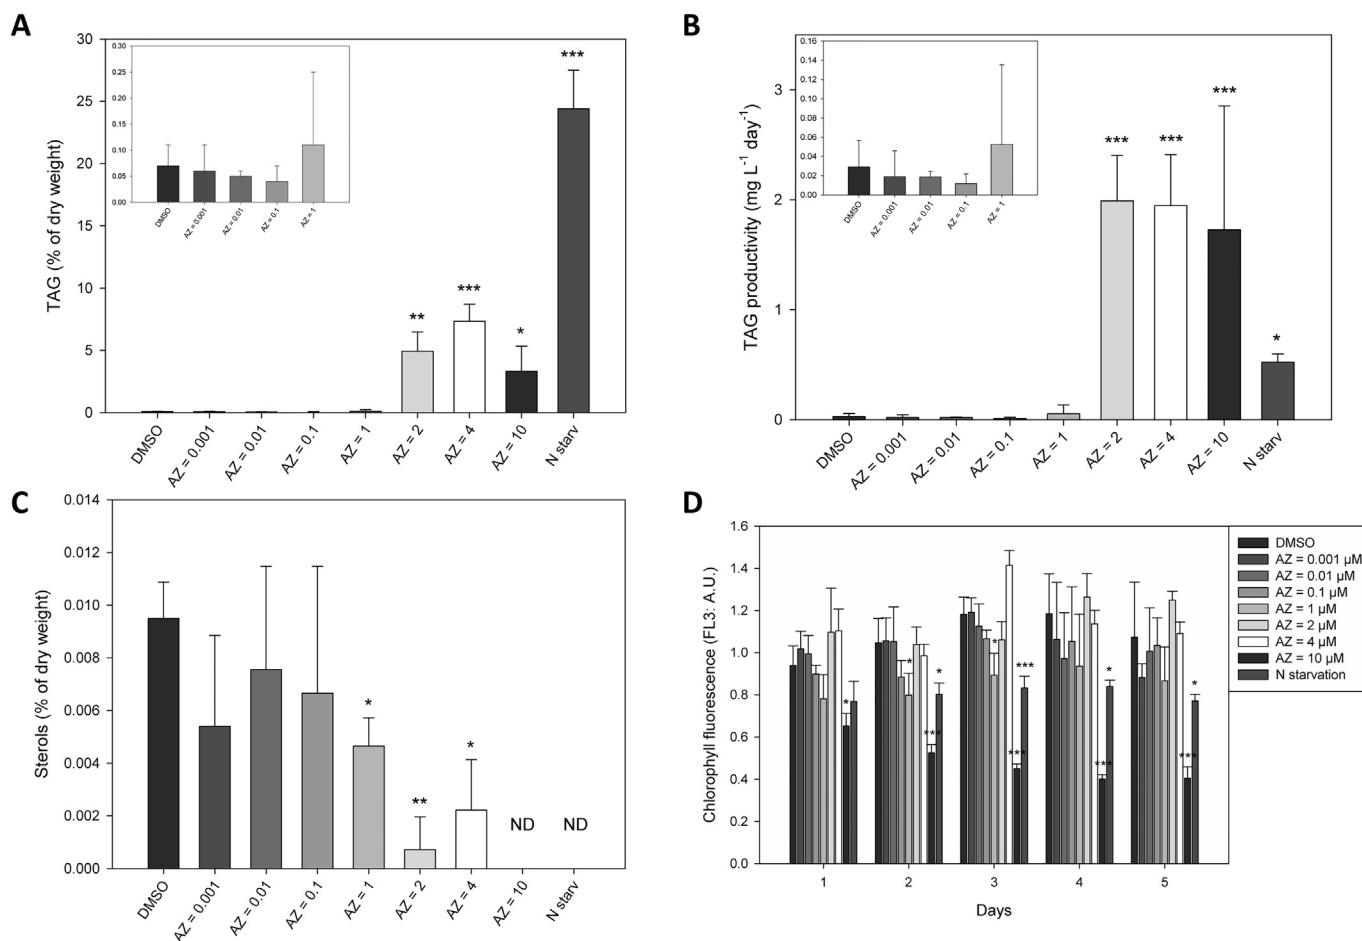

Fig. 3. Quantification of neutral lipid, sterols, and chlorophyll in batch cultures 5 days after addition of AZD-8055 (AZ) or N starvation. Neutral lipid and sterol content was estimated by TLC-FID analysis. A) Quantification of TAGs per culture batch relative to biomass. B) TAG productivity. C) Quantification of total sterols per culture batch relative to biomass. D) Chlorophyll auto-fluorescence. The means of three biological and three technical replicates are shown \pm standard deviation. Asterisks indicate statistical significance with respect to the control (* = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$).

3.6. Effect of AZD-8055 and N starvation on *P. tricornutum* metabolism

The activity of several metabolic enzymes was analyzed after 5 days of AZD-8055 treatment or N starvation. The activity of the NAD⁺-dependent glyceraldehyde 3-phosphate dehydrogenase (GAPDH) from glycolysis decreased significantly (> 2 -fold) following AZD-8055 treatment (Fig. 4A) and showed a dose response effect from 0.1 mol l^{-1} . On the contrary, GAPDH activity increased significantly under N starvation, suggesting that the two treatments may have different effects on glucose metabolism. The activity of malate dehydrogenase (MDH) from the Krebs cycle (Fig. 4B) was not affected in cells treated up to 2 mol l^{-1} AZD-8055 and increased significantly (2–3 fold higher than the control) in cells treated with the highest AZD-8055 concentrations (4 and 10 mol l^{-1}) as well as in cells subjected to N starvation. The activity of glucose-6-phosphate dehydrogenase (G6PDH) from the pentose phosphate pathway (Fig. 4C) was not affected in cells treated with up to 4 mol l^{-1} of AZD-8055, but at 10 mol l^{-1} of AZD-8055, we observed a significant increase of > 10 -fold with respect to the control. The increase in G6PDH activity under N starvation was similar to that obtained with the highest AZD-8055 concentration and was around 20-fold higher than in the control. The different activities of GAPDH in cells treated with AZD-8055 or N-starvation are intriguing and suggest that, despite other similarities, these treatments may have distinct effects on the primary metabolism of *P. tricornutum*, although this needs further investigation.

3.7. WYE-132, another specific ATP-competitive TOR inhibitor inhibits cell proliferation and promotes TAG accumulation in *P. tricornutum*

We tested other TOR inhibitors to confirm that the effects of AZD-8055 on cell proliferation (Fig. 5A) and neutral lipid accumulation (Fig. 5B) are specific to the inhibition of TOR. We found that rapamycin (10 μM) did not have a significant effect on cell proliferation with respect to the control and did not induce lipid accumulation. Problems with the potency of rapamycin have been reported in other photosynthetic organisms and we did not test higher concentrations of rapamycin as it leads to precipitates that could preclude clear conclusions [25–27]. The selective ATP-competitive TOR inhibitor WYE-132, which has been shown to be highly potent in plants [25], drastically inhibited cell proliferation and induced neutral lipid accumulation. These results were similar to those obtained when cells are deprived of N or exposed to high concentrations of AZD-8055 (40 μM). This indicates that WYE-132 is 10 times more potent than AZD-8055, as in plants [25], and that WYE-132 causes similar effects on cell proliferation and neutral lipid accumulation. These results strongly suggest that these effects are a specific response to the direct inhibition of TOR. Our observation that high concentrations of TOR inhibitors strongly inhibit cell proliferation suggests that under these conditions *P. tricornutum* TOR is fully inhibited. However, neutral lipid accumulation reached similar values at 10 μM and 40 μM AZD-8055 (Fig. 5B), suggesting that a concentration $\leq 10 \text{ μM}$ is sufficient to induce a maximum effect on lipid synthesis without completely impairing cell proliferation.

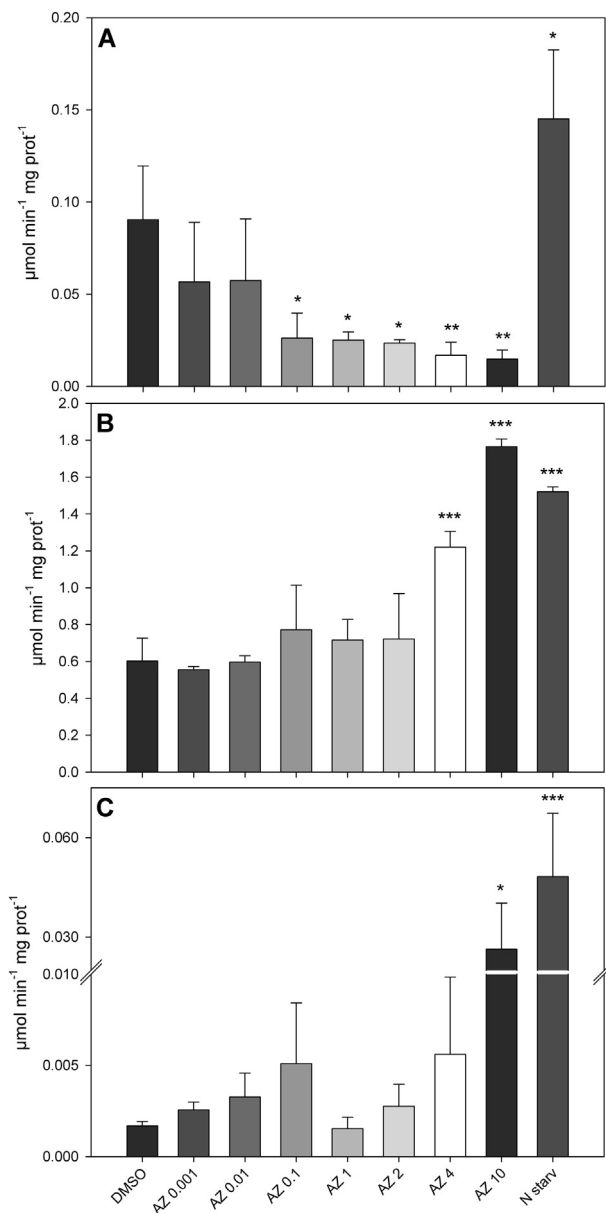

Fig. 4. Activity of metabolic enzymes in crude extracts from *P. tricornutum* cells 5 days after AZD-8055 (AZ) treatment or N starvation. A) NAD^+ -dependent glyceraldehyde-3-phosphate dehydrogenase (GAPDH), B) malate dehydrogenase (MDH) and C) glucose-6-phosphate dehydrogenase (G6PDH). The means of three biological and three technical replicates are shown \pm standard deviation. Asterisks indicate statistical significance with respect to the control (* = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$).

4. Discussion

It is widely recognized that microalgae can produce large amounts of lipids under certain stress conditions, most notably nutrient limitation, and that they are attractive for biofuel production [3]. Nevertheless, while redirecting energy towards lipid synthesis, the stressed microalgae also interrupt cell division [14]. As a consequence, the final lipid yield per culture is limited to the number of cells present when the lipid-induction process is initiated, even though cells accumulate neutral lipids as a large part of their biomass. This is one of the reasons why the production of third generation biofuels on a large scale is still not economically viable. In this work, we investigated whether the inhibition of TOR, a key player in the control of metabolic homeostasis and lipid biosynthesis [15,39,40], could promote “get-fat growth” in *P. tricornutum*, a regime under which lipid accumulation is promoted

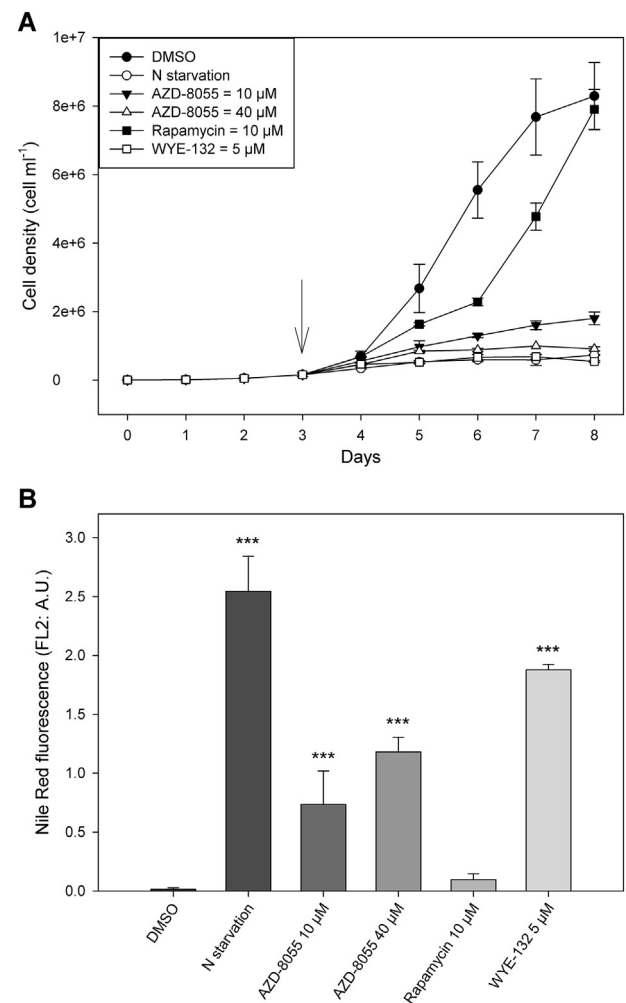

Fig. 5. Effect of different inhibitors of TOR and N starvation on *P. tricornutum* cell proliferation and neutral lipid fluorescence. A) Growth curves with the corresponding cell densities. The arrow indicates the day at which the treatment started. B) Lipid estimation after Nile red staining measured with the flow cytometer at 5 days after treatment. Means of at least three biological replicates are shown \pm standard deviation. Asterisks indicate statistical significance with respect to the control (* = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$). while maintaining cell proliferation.

Our work was the first attempt to inhibit the TOR kinase in a diatom. Rapamycin did not robustly inhibit *P. tricornutum* cell proliferation confirming that this allosteric inhibitor is generally less efficient in photosynthetic organisms than it is in yeast and mammalian cells [25]. The two specific ATP-competitive inhibitors of TOR, AZD-8055 and WYE-132, which have unrelated molecular structures and are potent in plants [25], inhibited *P. tricornutum* cell proliferation in accordance with the essential function of TOR in the regulation of cell growth and division, conserved in all organisms. Both TOR inhibitors also induced neutral lipid accumulation supporting the specificity of this response towards TOR inhibition. We focused our detailed analysis on AZD-8055 treatments because it has been shown to be effective in a large range of species of Viridiplantae including *Arabidopsis thaliana*, *Nicotiana benthamiana*, *Lotus japonicus*, *Panicum miliaceum* and *Oryza sativa*, [25] as well as in the microalga *C. reinhardtii* [16]. AZD-8055 is a potent ATP-competitive inhibitor of the mammalian TOR kinase that shows a high selectivity for mTOR and has almost no effect on other kinases including the closely related PIKK family members ATM, ATR and DNAPK [28]. Our demonstration here that AZD-8055 is potent in a diatom strongly suggests that AZD-8055 can be used to study the TOR

pathway in evolutionary distantly-related organisms as inhibition proceeds through the active site of the kinase, which is usually conserved among species. Indeed, we report here that the kinase domain of *P. tricornutum* TOR is closer to the corresponding domain in mammals than even flowering plants (Fig. S1). Our phylogenetic data thus suggests that it was the TOR kinase of the bikont host that was retained after the secondary endosymbiosis of red algae. Treatment of *P. tricornutum* cells with AZD-8055 resulted in a reproducible dose dependent inhibition of cell proliferation (Fig. 1A). Inhibition of proliferation was accompanied by an increase in TAG (Fig. 3A) and a decrease in sterols (Fig. 3C) and chlorophyll fluorescence (Fig. 3D). A similar inverse relationship between TAG and sterol production has been reported in photosynthetic [41,42] and non-photosynthetic organisms [43]. Sterols are usually more abundant during the exponential phase of cell growth when there is a high demand for lipids for membrane synthesis [44]. AZD-8055 caused a decrease in sterol levels even at concentrations that did not alter cell proliferation, suggesting that *P. tricornutum* sterol metabolism may be highly sensitive to TOR activity (Fig. 3C). The most abundant and almost only sterol found in *P. tricornutum* is epibrassicasterol (24 α -methylcholesta-5,22E-dien-3 β -ol or diatomsterol; [45]). Our data are in agreement with these findings and, while we found strong inhibition of free sterol accumulation in response to AZD-8055 and N-starvation, we did not observe any changes in sterol composition. Interestingly, cells treated with 10 μ M AZD-8055 had lower chlorophyll fluorescence than N-starved cells (Fig. 3D), despite a higher rate of proliferation. A study of *A. thaliana* plants treated with AZD-8055 reported the bleaching of leaves accompanied by the downregulation of genes involved in chlorophyll biosynthesis and an upregulation of genes involved in chlorophyll breakdown [46]. This suggests that the *P. tricornutum* TOR kinase has acquired similar functions to the plant TOR kinase in the control of chlorophyll metabolism, despite their different evolutionary histories. The AZD-8055 dose response curve also allowed us to reveal that AZD-8055 can promote a much higher TAG productivity than N starvation (Fig. 3B). This is because TAG could be induced at levels of AZD-8055 that reduced but did not stop proliferation as occurs in N starved cells. Recent studies show that the induction of TAG accumulation upon TOR inactivation appears to be a common trait in different types of organisms, both photosynthetic [15–18] and heterotrophic [47]. However, inhibition of TOR for the modulation of TAG productivity has not been clearly investigated. Indeed, the rapamycin concentration used to promote TAG accumulation in red and green algae almost completely inhibits cell proliferation [17,26,48]. Interestingly, rapamycin did slightly increase neutral lipids per cell in *Euglena gracilis* at a concentration that also had little effect on proliferation [18]. Taken together with our demonstration here that TAG productivity is promoted by treatment with AZD-8055 in *P. tricornutum*, this strongly suggests that increased TAG productivity may be a common response of algae to partial TOR inhibition. We looked for the effect of AZD-8055 on the activities of metabolic enzymes representative of central pathways for cell physiology. We measured the activity of GAPDH from glycolysis, of G6PDH from the oxidative pentose phosphate pathway and MDH from the Krebs cycle. Previous studies showed that these enzymes have a connection with lipid metabolism in nutrient limited microalgae [8,49,50]. Enzyme activities were measured in AZD-8055 treated cells and cells under N starvation to determine whether similar metabolic responses underlie TAG accumulation under these two conditions. The activity of GAPDH clearly decreased in AZD-8055 treated cells while it increased in response to N starvation. The increase in GAPDH activity under N-starvation is consistent with previous studies showing that the transcript levels of GAPDH_3, which encodes the cytosolic GAPDH, increase in response to N-starvation [51,52]. Increased GAPDH is also consistent with increased TAG accumulation because the final products of glycolysis are ATP and pyruvate, the primary sources of energy and carbon for lipid synthesis [53]. It is therefore all the more surprising that AZD-8055 treatment simultaneously inhibited glycolysis and promoted TAG

accumulation. The impaired glycolytic reactions under TOR inactivation, even at low concentrations of AZD-8055, suggest that the TOR signaling cascade may have a direct effect on sugar metabolism. A direct correlation between mTOR and glycolytic activity has been observed in different animal cell lines [54–57]. The activities of G6PDH and MDH, as for cell proliferation, were affected only at the highest concentrations of AZD-8055 and increased to values comparable with those of cells under N starvation. This is consistent with previous transcriptomics analyses showing increased accumulation of transcripts coding for enzymes of the Krebs cycle and the pentose phosphate pathway upon N starvation in *P. tricornutum* [51]. Furthermore, a correlation between the activity of G6PDH and MDH and TAG synthesis has previously been demonstrated [8,50]. The higher activity of G6PDH probably provides a stock of NADPH that could be used for lipid synthesis. On the other hand, a higher MDH activity may reflect a higher activity of the whole Krebs cycle, supplying the lipid biosynthesis pathway with carbon skeletons (e.g. citrate for the synthesis of cytosolic acetyl-CoA; [53]). In summary, the enzyme activity assays and measures of chlorophyll fluorescence show that AZD-8055 treatment and N-starvation provoke both common and divergent metabolic responses. Notably, in animals and yeast TOR activity is inhibited by low nitrogen availability [57]. If this is also the case in *P. tricornutum* then it suggests that N starvation, in addition to also potentially inhibiting TOR, may also activate other signaling pathways to promote TAG accumulation. Further studies are, therefore, clearly required to better understand the different mechanisms that appear to orchestrate TAG production under TOR inhibition and N-starvation.

As we have shown, AZD-8055 treatment has multiple effects on cell physiology and metabolism in *P. tricornutum*. In particular, we found that the specific TOR kinase inhibitor AZD-8055 had dose dependent effects on cell proliferation, lipid homeostasis, chlorophyll accumulation and carbon metabolism. The TOR pathway is still under study in plants and has so far received little attention in diatoms [58]. The direct targets of TOR involved in downstream signaling cascades, gene transcription, and protein synthesis remain to be discovered. Our finding that, in contrast to other TOR inhibitors, the inhibition of the TOR kinase at intermediate concentrations of AZD-8055 promotes high TAG productivity while reducing but not halting cell proliferation, paves the way for new studies on TOR signaling in diatoms as well as for the chemical and metabolic engineering of algae for high lipid production.
